INTRODUCTION
During the last two decades, social anxiety disorder has gradually been known as one of the most prevalent psychological chronic disorders, and the most prevalent anxiety disorder.

In severe cases, social anxiety can reduce the quality of life for the person to the extent that some of the patients might refuse to leave home for weeks, or waiver many social opportunities such as occupational or educational ones.

Epidemiology studies report that the prevalence of social anxiety is 3 to 13 percent.

A 13-percent prevalence puts this disorder in the third position of psychological disorders in the society after depression and alcoholism.
It is a type of disorder which usually results in a long period of disability and the patients suffer significant damage in their daily social and professional life.

Social anxiety or fear of embarrassment in functional or social situations is the most prevalent anxiety disorder which affects the adult functioning at home or at work.

It has weakening effects and is one the most common psychological disorders with a prevalence lifespan of 3 to 13 percent.

Various genetic factors, personal characteristics, and cognitive-behavioural elements play a role in social anxiety; how the total outcome of these factors form this disorder is what considered in the prediction of its outbreak and severity.
Many variables are related to social anxiety that could be a factor or an outcome of this disorder.

One issue related to managing one’s emotional reactions to others is self-control.

Self-control is intrapersonal conflict between logic and lust, cognition and motivation, and internal planning and internal factor.

It is an important concept which determines an individual’s behaviour, and a force for inhibition, rejection, and modification of responses that are a consequence of psychological processes, habits, learning, or situational pressure.
Self-control, to the most part, is a result of parental discipline in childhood.

In fact, a significant part of psychological pathology in children and adults is about insufficiency of self-control.

Self-control in childhood has various positive outcomes in adulthood, such as less delinquency, reduced drug use, improved sexual performance, higher education, and better job opportunities.

However, the intervention of other factors-gender, economic and social conditions, IQ, and childhood conduct disorder-in the relationship between self-control and the aforementioned outcomes should be noted as well.
In any case, social anxiety has severe negative effects on psychological, personal and social health of patients.

High levels of unemployment, absence from work and low quality of life, are socio-economic outcomes of this disorder.

In addition, anxiety, anger, hostility, verbal aggression, and borderline tendencies are cases which have negative significant correlation with self-control.

For Example, Tangie, Bumster, and Bune (2004) showed that university students with high self-control show better psychological adjustment and do better in interpersonal relations.
Among recently emerged treatments in the area of cognition in psychology is Mindfulness-Based Cognitive Therapy (MBCT).

Mindfulness is a type of consciousness formed when there is open attention to experience around a specific subject, a focused attention on the target (openly on specific aspects of experience) in the present and without judgment (about what has happened).

Mindfulness-based cognitive therapy was developed from Kabat-Zinn’s model of mindfulness-based stress reduction with cognitive treatment principals added to it later.
This type of cognitive therapy includes different meditations, stretch yoga, an introduction to depression, practicing body review, and a number of cognitive therapy exercises, that show the relationship between creation, thoughts, emotions, and physical senses.

Mindfulness-based cognitive therapy, which is a non-judgmental process of attention to the present experience, has been widely incorporated into the treatment of a range of psychological disorders such as depression and anxiety.

Studies on treatment outcomes have supported the effectiveness of mindfulness-based cognitive therapy on depression and anxiety.
This therapy, which is a short-term 8-session structured intervention, is based on Kabat-Zinn’s model of mindfulness stress reduction (1990) with added cognitive therapy principles.

The goal here is not to manipulate thoughts, but to create a different attitude towards thoughts, emotions, and feelings. This encompasses full open attention on the moment, as well as non-judgmental acceptance.

Mindfulness-based cognitive therapy includes a number of different techniques derived from mindfulness mechanisms.

Many studies have offered suggestions for a more targeted application of mindfulness techniques based on specific signs of depression and anxiety.
Additionally, mindfulness-based cognitive therapy includes five prevalent mechanisms:

1) **Description:** The ability to describe internal experiences by words.
2) **Observation:** The process of observing or paying attention to internal and external experiences.
3) **Mindfulness Action:** Doing current activities at the present is usually compared with acting automatically.
4) **Lack of Judgment:** Accepting a non-judgmental point of view towards thoughts and emotions.
5) **Lack of Reaction:** Letting thoughts and emotions to come and go without reacting or trying to amend them.
The mechanism of MBCT against anxiety cognitive patterns includes:

a) decentralization (the ability to focus on the present and being non-judgmental about thoughts and feelings, and accepting them)

b) changing the state of doing to the state of being (this is a key component of MBCT which helps patients to decentralize). The state of doing includes thinking a lot about past and future, and not being in the present.

However, the state of being is a state of no effort and no judgment. Decentralization is similar to the mind’s state of being. The state of doing is when there is a difference between how things are and they are supposed to be, as determined by the mind.
Christopher et al. (2012) showed that a positive relationship exists between mindfulness-based cognitive mechanisms and symptoms of depression and anxiety.

Others also showed reduced anxiety symptoms with mindfulness-based cognitive therapy.

A study by Fisak and von Lehe (2012) reported that in mindfulness-based cognitive therapy, being non-responsive reduces anxiety.

This is because letting thoughts and feelings to enter consciousness, without reacting to them or trying to amend them (i.e. worry and rumination), is useful for reducing continuous negative thought processes which are prevalent in the anxiety disorder.
De Bruin, Topper, Muskens, Bogels, and Kamphuis (2012) also showed that mindfulness-based cognitive therapy reduces worry and rumination.

Regarding the effectiveness of mindfulness-based cognitive therapy on social anxiety and self-control, no study has been conducted so far in Iran.

Therefore, this study aims to answer the question that whether mindfulness-based cognitive therapy (MBCT) affects anxiety and self-control in patients with social anxiety.
Hypotheses

- Mindfulness-based cognitive therapy affects social anxiety symptoms in patients with social anxiety.

- Mindfulness-based cognitive therapy affects self-control in patients with social anxiety.
Research Methodology

The present study was quasi-experimental with pre-test, post-test and follow-up with experiential groups
Population, Sample and Sampling Method

- The research population was the students of Isfahan University.

- Using the social anxiety scale test, the students with social anxiety were diagnosed.

- At the end, 30 students were selected through purposive sampling, and were randomly divided into experimental and control groups.

- The selection criteria was: a score of greater than 70 in Liebowitz Social Anxiety Scale (LSAS), no cardiovascular diseases, no psychological illnesses such as bipolar disorder and psychosis, and no addiction.

- The criteria for eliminating a participant was: being absent for more than two intervention sessions, and lack of consent for receiving therapy.

Data Gathering Tools
Liebowitz Social Anxiety Scale (LSAS): created by Liebowitz in 1987, it is the first medical tool that evaluates a wide range of social situations that are difficult to face with for social anxiety patients.

- It is a questionnaire with 24 items. Scoring 55 to 65 indicates low social anxiety, while 55 to 80 and 80 to 95 are indicators of average and severe social anxiety respectively.

- Scoring 95 or more shows that the person suffers from highly severe social anxiety.

- The total Chronbach’s Alpha for this scale is 0.95, performance anxiety subscale Chronbach’s Alpha is 0.82, and social anxiety subscale Alpha is 0.91
**Self-Control Scale:** This measure was made by Tangney (2004). It is a questionnaire with 36 items that is design based on Likert scale.

In Iran, reliability of this test was measured by Rafiei and Janbozorgi (2010) and they obtained a Chronbach’s Alpha of 0.89.

In addition, the re-test coefficient and Chronbach’s Alpha of self-control questionnaire was 0.88 and 0.80 respectively.
METHODOLOGY
Both groups took a pre-test of social anxiety and self-control.

The experimental group received an 8-session mindfulness-based cognitive therapy (MBCT) intervention.

At the end, both groups took a post-test of the aforementioned variables.

A follow-up test was given after one month and the results were analyzed.

Table 3 shows the descriptive statistics index of social anxiety of subjects in experimental and control groups in pre-test, post-test and follow-up.

As shown in table 3, mean social anxiety in the experimental group was 85.06 in pre-test, 76.53 in post-test, and 82.40 in follow-up.

Mean social anxiety in the control group was 83.33 in pre-test, 77.06 in post-test, and 81.73 in follow-up.

</table>
The results of variance analysis in Table 7 show that by controlling significant relationships between pre-test scores and post-test and follow-up scores of social anxiety (p < 0.01), the difference between the justified mean of experimental and control groups at post-test (p < 0.01) and follow-up (p > 0.05) is significant.

Regarding justified means of the two groups, it can also be concluded that mindfulness-based cognitive intervention has reduced behavioural inhibition by 12.37% in post-test, and 6.8% in follow-up.

In addition, the statistical power of 97% shows the sufficiency of the sample and the acceptability of statistical accuracy.

As is shown in Table 14, justified mean of self-control of the experimental group is 107.12 in post-test and 109.02 in follow-up, and that of the control group is 115.21 and 115.50 respectively.
DISCUSSION
The first hypothesis – mindfulness-based cognitive therapy affects the level of anxiety in social anxiety patients – was confirmed.

The results showed that this treatment improves social anxiety in these patients.

This finding confirms to the findings of a number of other studies: Gonzalez, Vajanwick, Johnson, Laier, and Volenski (2009), Abramson et al. (2002), and Fisak and Van le (2012) suggested that mindfulness-based cognitive therapy reduces anxiety.

That is because letting thoughts and feelings enter consciousness without reacting to them or trying to amend them is useful for reducing negative thoughts that are prevalent in both depression and anxiety.
Debrion, Taper, Masenz, Bogelz, and Comfemis (2012) also showed that mindfulness-based cognitive therapy reduces worry and rumination. This finding was confirmed by Fisk et al. (2012), and De Bruin et al. (2012).

On the other hand Gerlach et al. (2003) showed that social anxiety has severe negative effects on the psychological, personal and social health of the patients.

In this respect, the two main mechanisms of MBCT against cognitive anxiety patterns includes:

a) decentralization (the ability to focus on the present with no judgment about thoughts and feelings; the state of accepting)

b) being instead of doing (changing the state of doing to the state of being is a key component of MBCT which helps patients to decentralize).
In fact, mindfulness-based interventions with the purpose of reducing psychological symptoms of distress (Kabat, 1990) are increasingly applied in the field of psychological health (Gerousmen, 2011).

The aim of these interventions is to create a clear non-judgmental mindfulness about everything happening in the perception at any consecutive moment.

Most of the time, psychological suffering can be traced back to the judgmental mind which divides experiments into good ones and bad ones, and dictates that one should fight or avoid, and therefore, a range of negative feelings such as failure, distress, anxiety and depression (Micky Leak, 2008).
By reducing the presence of judgmental mind and decentralizing, we can reduce worry and anxiety.

The major skill learnt when practicing mindfulness is to release oneself from rumination, negative thoughts, and self-continuation, which are part of the state of doing.

In the state of being, the focus is on accepting whatever present at the moment, without trying to change anything.

In the state of being, there is no effort for analyzing future outcomes, finding solutions for potential problems, or reviewing previous efforts for solving similar problems.
Instead of thinking about problems or situations, in the state of being one tries to directly observe and accept whatever happening in the present, including thoughts and feelings which require instant action.

This mindfulness attitude towards thoughts and feelings, slows down reactivity against others, and increases the ability to choose new answers.

It also increases rumination, reinforces acceptance of thoughts and feelings, and weakens the tendency to consider these thoughts and feelings as necessarily precise reflections of the truth about self or the world.

Therefore, using these new skills, one can experience sadness without automatically intensifying anxiety.
The second hypothesis – mindfulness-based cognitive therapy affects self-control in patients with social anxiety—was confirmed.

The results showed that this treatment improves self-control in these patients. This conforms to findings of a number of other studies.

*For Example*, Rasoul Zadeh (2014) studied cognitive therapy based on acceptance and commitment.

The results showed reduced social anxiety and improved assertiveness and inconsistent beliefs, as well as the justifying role of emotional regulation.

The theoretical implications of these findings are worth noting, since no other study has specifically considered self-control.

Therefore, since self-control determines one’s behaviour, it is a force of inhibition, rejection, and change of responses as a result of psychological processes, habits, learning, or situational pressures.
One of the major problems in social anxiety is experimental avoidance (an activity to change the form, the content, the frequency, or the duration of an unwanted personal experiment) (Hayes and Giford, 1997).

This experimental avoidance manifests itself in to forms: escaping from annoying experiments or distancing from situations related to the initiation of those mental experiments, and behavioural suppression.

This avoidance can temporarily reduce anxiety and its symptoms, however, it has long-term negative social, psychological and even physical effects (Hayes, 2004).

Kobat Zinn (1992) suggested a number of approaches regarding the potential effects of mindfulness on anxiety and fear: constantly monitoring the senses related to anxiety, without judgment and without trying to escape or avoid, can reduce emotional reactions that were invoked by anxiety.
As Linhan (1993) pointed out in his study, patients with borderline personality disorder suffer from emotional phobia; these people are frightened to experience severely negative emotions. This fear is understandable, since their negative emotional states are generally intense.

However, their effort to avoid these states usually has inconsistent outcomes.

Observing present thoughts and emotions, without trying to avoid them, can be a kind of confrontation that prevents fear responses and automatic reactions reinforced by fear-provoking stimuli; therefore, the ability to tolerate negative emotions has positive effects that will in turn produce more adaptability and better social relationships.

In this respect the results of Tangie, Bumster and Bunn (2004) indicate that university students with higher self-control show better adaptability and interpersonal relationships; they also do better in their studies.
Mindfulness helps people to understand that negative emotions might exist, but they are not a permanent part of personality. It also provides an opportunity to respond to events with thinking and reflection, rather than involuntarily (Emanuel et al. 2010).

This type of awareness enables patients to see the provoking of rumination and negative reactions more clearly, and can decentralize such thinking patters, and see them as mental processes not representative of the truth (Mikey, 2008).

Ultimately, it helps the person to discover calmness and satisfaction in the deep of herself, and to bring it into her daily life; it helps the person to gradually free herself from worry, anxiety, fatigue, depression, and dissatisfaction.
Without mindfulness, the person will experience exhausting emotions mixed with bitter feelings, anger and severe insolvency (Williams and Penman, 2012).

It is justifiable by mindfulness-based therapy, that regarding avoidance behaviour against social situations, patients tend to consider short-term consequences of avoiding internal and external stimuli, which leads to negative reinforcement, and suffer the long-term consequences such as continuity and intensification.
According to the results of the present study, it is suggested that in treating social anxiety patients, mindfulness main processes and skills, together with other interventions such as awareness, decentralization, and releasing be specifically taken into account by therapists.

Regarding self-control, it is suggested that therapists use emotional regulation approaches in order to regulate responses related to fear and worry in social anxiety.

For better adaptation and better interpersonal relationships (that play an important role in improving social anxiety), it is also suggested that teaching communication skills be considered as part of the treatment.
CONCLUSION

- This study was conducted to assess the effectiveness of mindfulness-based cognitive therapy on severity of social anxiety and self-control people with social anxiety symptoms.

- The study was quasi-experimental with pre-test, post-test and follow-up with experiential groups.

- The results showed that mindfulness-based cognitive-behavioural therapy in reducing severity of social anxiety and improvement of self-control and psychological flexibility is effective in patients with social anxiety symptoms.

- According to the results of this research, mindfulness-based cognitive-behavioural therapy is an effective way to improve the factors that can have an important role in improving social anxiety.
Descriptive Statistics provide simple summaries about the sample and about the observations that have been made. Such summaries may be either quantitative, i.e. summary statistics, or visual, i.e. simple-to-understand graphs.

These summaries may either form the basis of the initial description of the data as part of a more extensive statistical analysis, or they may be sufficient in and of themselves for a particular investigation.
The **Quasi-Experimental Study Design**, sometimes called the pre-post-intervention design, is often used to evaluate the benefits of specific interventions.

- Quasi-experimental studies encompass a broad range of nonrandomized intervention studies.

- These designs are frequently used when it is not logistically feasible or not ethical to conduct a randomized, controlled trial—the “gold standard” of causal research design.
The **Shapiro–Wilk Test** is a test of normality.

It was developed in 1965 by Samuel Sanford Shapiro and Martin Wilk.
Analysis of Covariance (ANCOVA) is a model which blends ANOVA and regression.

ANCOVA evaluates whether the means of a dependent variable (DV) are equal across levels of a categorical independent variable (IV) often called a treatment, while statistically controlling for the effects of other continuous variables that are not of primary interest, known as covariates (CV) or nuisance variables.
The basic assumptions to be fulfilled before using ANCOVA are:

a) linearity of regression  
b) homogeneity of error variances  
c) independence of error terms  
d) normality of error  
e) homogeneity of regression slopes

\[ y_i = \beta_0 + \beta_1 X_i + \beta_2 Z_i + e_i \]

where:
- \( y_i \) = outcome score for the \( i^{th} \) unit  
- \( \beta_0 \) = coefficient for the intercept  
- \( \beta_1 \) = pretest coefficient  
- \( \beta_2 \) = mean difference for treatment  
- \( X_i \) = covariate  
- \( Z_i \) = dummy variable for treatment (0 = control, 1 = treatment)  
- \( e_i \) = residual for the \( i^{th} \) unit
The Title of the Paper is appropriate and in line with the aim of the study.
The authors have adequately addressed to the importance of MBCT, with especial reference to social anxiety.
Tools used for the assessment of social anxiety and self-control are appropriate.
Authors have, in detail, also explained the therapeutic package given to the patients.
Statistical package chosen was adequate and helped in achieving and analyzing the results.
The limitation of the study was sample size.
The sample size was small (30), therefore, result of the study could not be generalized.
Other variables, such as quality of life or depression could also be taken into consideration.
